**Abstract** We investigate the variation of bar strength with central velocity dispersion in a sample of barred spiral galaxies. The bar strength is characterized by  $Q_g$ , the maximal tangential perturbation associated with the bar, normalized by the mean axisymmetric force. It is derived from the galaxy potentials which are obtained using near-infrared images of the galaxies. However,  $Q_g$  is sensitive to bulge mass. Hence we also estimated bar strengths from the relative Fourier intensity amplitude ( $A_2$ ) of bars in near-infrared images. The central velocity dispersions were obtained from integral field spectroscopy observations of the velocity fields in the centers of these galaxies; it was normalized by the rotation curve amplitude obtained from HI line width for each galaxy. We found a correlation between bar strengths (both  $Q_g$  and  $A_2$ ) and the normalized central velocity dispersions in our sample. This suggests that bars weaken as their central components become kinematically hotter. This may have important implications for the secular evolution of barred galaxies.

## 1 Introduction

In past decades there has been a large amount of discussion regarding the secular evolution of bars in spiral galaxies. Numerical simulations show that gas inflow, star formation and the subsequent buildup of a central mass concentration (CMC) can considerably alter the shape of a bar and even result in the dissolution of the bar itself (Norman et al. 1996; Shen and Sellwood 2004; Kormendy and Kennicutt 2004; Hozumi and Hernquist 2005; Athanassoula et al. 2005; Bournaud et al. 2005). Some studies suggest that the fraction of bars remains high out to  $z \sim 0.7$  (Sheth et al. 2003; Elmegreen et al. 2004; Jogee et al. 2004) while others suggest a decline in the bar fraction by  $z \sim 0.8$  (Sheth et al. 2008). These observations suggest that bars evolve in galaxy disks. Simulations suggest that bars can dissolve but form again once the disk is cooled through gas accretion (Bournaud and Combes 2002) or through tidal interactions (Berentzen et al. 2004).

Although there has been a considerable amount of numerical work on bar formation and dissolution, there is not much observational evidence. Molecular gas has a higher central concentration in barred galaxies compared to non-barred galaxies which suggests that bars are important for building up a CMC (Sakamoto et al. 1999; Sheth et al. 2005). The bar length has been found to correlate with bar intensity contrast and central luminosity densities (Elmegreen et al. 2007). A more direct indicator of how bars change with mass concentration is the correlation of CMC and bar ellipticity (Das et al. 2003) which shows that bar ellipticity declines with increasing dynamical CMC. An enhanced CMC also results in the deepening of the central potential and gives rise to a dynamically hotter galaxy center. This will lead to a higher observed central stellar velocity dispersion in a galaxy ( $\sigma_v$ ). This effect has been

seen in numerical simulations where a dynamically hotter center results when a bar dissolves (Friedli and Benz 1993; Hasan et al. 1993) or weakens (Athanassoula et al. 2005). In this paper we investigate whether there is any observational evidence for this heating effect by examining the correlation between the central velocity dispersion in bars and the bar strength.

## 2 Central velocity dispersion

The  $\sigma_v$  values used in this paper are from published integral-field spectroscopy (IFS) observations of the nuclear re-

gions of galaxies. We have thirty one galaxies in our sample (Table 1). The majority of  $\sigma_v$  values are from the SAURON survey of nearby galaxies (de Zeeuw et al. 2002; Ganda et al. 2006; Falcón-Barroso et al. 2006; Peletier et al. 2007); a smaller number are from the INTEGRAL and SPIRAL instruments on the William Herschel and Anglo-Australian Telescopes respectively (Batcheldor et al. 2005). The  $\sigma_v$  values for the remaining four galaxies are from observations using the GMOS instrument at the Gemini North Telescope (Barbosa et al. 2006). The velocity dispersion val-

ues that we have used are derived from two dimensional stellar velocity fields and not gas kinematics.

One drawback of using these  $\sigma_v$  values is that the aperture size is not uniform across the sample. Hence we have tried to bring the apertures to a common system using the aperture correction formula of Jorgensen et al. (1995). The velocity dispersions were corrected to a radius  $R_e/8$ , where  $R_e$  is the effective bulge radius of a galaxy. Thus  $\sigma_v$  was assumed equal to the average velocity dispersion within a radius  $R_e/8$  of the bulge of a galaxy. For five galaxies it was not possible to determine  $R_e$  either because the bulge was not distinguishable or the image quality was poor. Also, since the galaxies span a wide variety of size and mass, we normalised the new aperture corrected velocity dispersions ( $\sigma_e$ ) with the HI gas rotation velocity  $v_g$  for each galaxy. This also takes out some of the luminosity/size effects for the galaxies. The  $v_g$  values were derived from the maximum HI rotation velocities ( $v_H$ ) using the galaxy axes ratios ( $q$ ) to correct for inclination (i.e.  $v_g = v_H/\sqrt{1-q^2}$ );  $v_H$  was obtained from the HyperLeda database. The ratio  $\sigma_e/v_g$  is thus an indicator of how kinematically hot the center is for each galaxy relative to its disk rotation speed.

### 3 Bar strength derived from near-IR images

There are several ways to quantify the strength of a bar in a galaxy. In this paper we have derived the bar strength in two ways; bar strength is assumed to be the maximum relative bar torque ( $Q_g$ ) derived from the gravitational potential of a galaxy. This is probably the most robust estimate of bar strength but it is sensitive to the bulge mass or luminosity. The second way of estimating bar strength is to use the maximum of the relative intensity amplitude of the bar in the near-IR image ( $A_2$ ). Both methods require that the images be deprojected before analysis. This assumes the disks are thin, but the presence of a less flattened bulge component could lead to artificial stretching of bulge isophotes. To minimize this effect, we decomposed the bulge from the disk, subtracted it from the image before deprojection, and added it back (assuming that bulge light is spherically symmetric) after deprojecting the disk/bar light. The bulge components were separated from the disks using a two-dimensional multicomponent decomposition code which uses a Sersic model for the bulge, an exponential function for the disk, and either Ferrers' or Sersic's functions for the bar (Laurikainen et al. 2005). Effects of seeing were taken into account, using the values of the full width at half maximum stored in image headers or provided in articles. The effective radius of the bulge ( $R_e$ ) was estimated by integrating the flux of the fitted bulge model. The images were obtained mainly from the 2MASS survey and some from previous studies. The filters used were either K or H band. The bar parameters were derived as follows.

- (i)  $Q_g$  The gravitational potentials ( $\Phi$ ) were inferred from near-IR light distributions assuming that the light traces the mass. Bar induced tangential forces were calculated using a Polar method, as described in Laurikainen and Salo (2002) and Laurikainen et al. (2004). In particular, the calculation applies an azimuthal Fourier decomposition of intensity, including the even components up to  $m = 20$ , which are then converted to the corresponding potential components (Salo et al. 1999). Two dimensional maps of the radial force ( $F_R$ ) and tangential force ( $F_T$ ) were calculated. The radial profile of the maximum tangential force at each distance is given by,

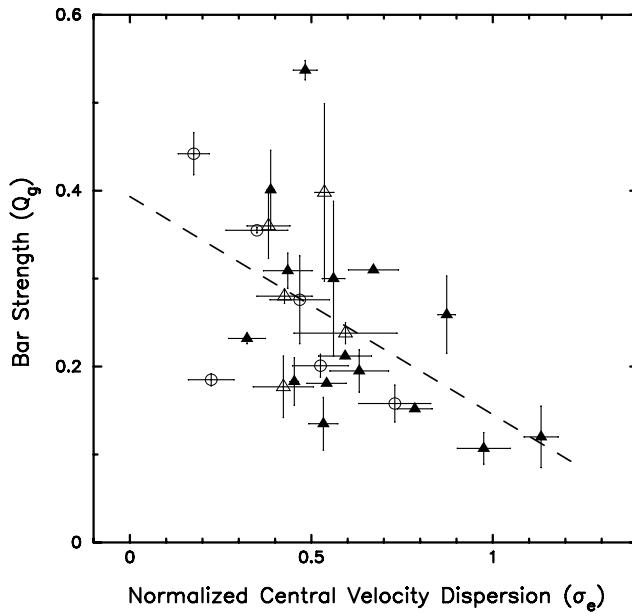

$$Q_T(r) = \frac{|F_T(r, \phi)|_{max}}{\langle |F_R(r, \phi)| \rangle} \quad (1)$$

where  $\langle |F_R(r, \phi)| \rangle$  denotes the azimuthally averaged axisymmetric force at each radius. The maximum in the  $Q_T$  profile at the region of the bar then gives a single measure of bar strength,  $Q_g$ . The main assumptions are that the mass-to-luminosity ratio is constant in the bar region, and that the vertical light distribution can be approximated by an exponential. The scale height,  $h_z$ , was estimated from an empirical relation between  $h_r/h_z$  and the de Vaucouleurs type index T (de Grijs 1998), where  $h_r$  is the radial scale length of the disk. The images were taken from the literature and are generally not very deep. Therefore, instead of estimating  $h_r$  from the new decompositions, we used mainly the  $h_r$  values from Baggett et al. (1998); if it was not available, we used other sources in the literature where deep optical images had been used to derive  $h_r$ . For two galaxies  $h_r$  was taken to be the mean value for our sample of 31 galaxies.

- (ii)  $A_2$  The same Fourier method gives us also the  $m = 2$  amplitudes of bar intensity contrast in the bar region. For some of the galaxies, Table 1 gives  $Q_g$  and  $A_2$  but not the effective bulge radius. This is because application of the 2D decomposition method requires deeper images than the methods used to calculate  $Q_g$  and  $A_2$ .

### 4 Estimating the correlation

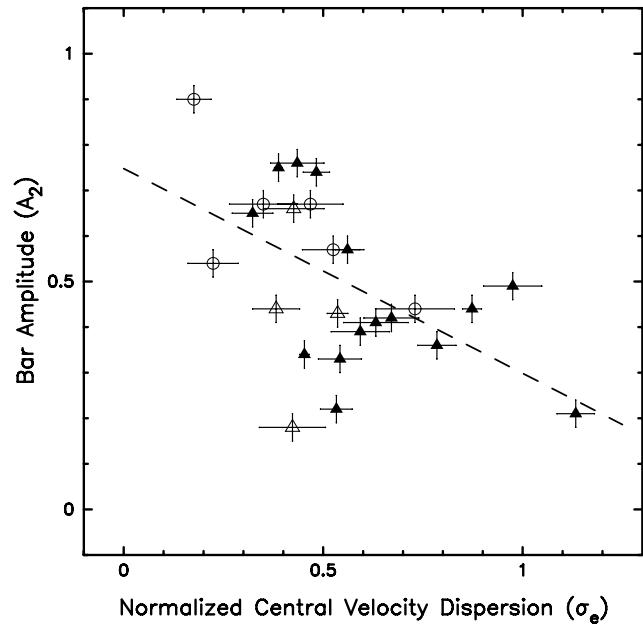

Figure 1 shows bar strength  $Q_g$  plotted against the normalized velocity dispersion  $\sigma_e/v_g$  for 26 galaxies. Although there are 31 galaxies in the sample, we could use only 26 because the effective radius  $R_e$  could not be calculated for a few cases. The errors have been calculated using the standard error propagation equation and include the uncertainties in the observed quantities. The majority of galaxies seem to follow a trend of decreasing bar strength with increasing central velocity dispersion. We quantified the correlation in two ways. The linear correlation coefficient for

**Fig. 1** The plot shows the bar strength  $Q_g$  plotted against the normalized central velocity dispersion ( $\sigma_e/v_g$ ) for 26 galaxies from Table 1. The three galaxy types are S0/a to Sa (open circles), intermediate-type spirals are Sab to Sbc (filled triangles) and the late-type spirals are Sc to Sd (open triangles). The errors are marked on each axis. The dashed line is the best fit line and has the form  $y = -0.25x + 0.39$ . Although there is some scatter, the overall trend suggests that bars weaken as their nuclei become dynamically hotter

this sample of 26 galaxies is  $r = -0.50$  and the probability that they are from a random sample  $P_r$  is  $P_r < 1\%$ . This method does not include the errors on both axes. A more accurate estimate would be a weighted correlation coefficient, but this is difficult to obtain in practice (Feigelson and Babu 1992). Instead we used a simple Monte Carlo simulation that randomly samples the errors on both axes and determines a mean weighted correlation coefficient  $\langle r \rangle$ . We used 50,000 linear fits and obtained a value of  $\langle r \rangle = -0.46$ . The second method that we used to quantify the correlation was the Kendall-Tau coefficient which assigns relative ranks to the different values. This is perhaps a more robust way of examining the correlation especially when the sample size is relatively small as in our case. The Kendall-Tau coefficient for the 26 galaxies in Fig. 1 is  $\langle r_{KT} \rangle = -0.35$  and the probability that they are from a random sample is  $P_{KT} \sim 1.3\%$ .

Figure 2 shows the plot of  $A_2$  against the normalized velocity dispersion  $\sigma_e$  for 25 galaxies. Here again we calculated the linear correlation coefficient which is  $r = -0.54$  and  $P_r < 0.5\%$ . When the errors are sampled using a Monte Carlo simulation we obtain a value of  $\langle r \rangle = -0.51$ . The Kendall-Tau coefficient for the 25 galaxies is  $\langle r_{KT} \rangle = -0.33$  and  $P_{KT} < 2\%$ . Thus both Figs. 1 and 2 suggest that there is a correlation between the bar strength in galaxies and their central velocity dispersions.

**Fig. 2** The plot shows bar amplitude  $A_2$  measured from the near-IR images plotted against the normalized central velocity dispersion ( $\sigma_e/v_g$ ) for a sample of 25 galaxies. As in Fig. 1 the open circles represent early type spirals, the filled triangles represent intermediate type spirals and the open triangles represent the late type spirals. The dashed line is the best fit line for the sample and has a form  $y = -0.45x + 0.75$

## 5 Discussion

The main result of this paper are shown in Figs. 1 and 2. There are 26 galaxies in the plots of which about half are intermediate type spirals and the remaining a mixture of early and late type spirals. Since the number of galaxies in each Hubble type is not very large, we cannot investigate trends within the different Hubble types. But from Figs. 1 and 2, it appears that early type spirals have relatively lower central dispersions; this may be because they have larger bulges where rotational velocity is comparatively higher and the central velocity dispersion lower compared to the later Hubble types.

Since the correlation is significant but not very strong we examined the two galaxies that define the higher and lower limits of  $Q_g$  and  $A_2$ . We looked at them closely to see if they are odd in some way, and not characteristic of the rest of the sample. (i) NGC 3162 ( $\sigma_e/v_g = 1.13$ ): This is an intermediate type spiral galaxy with a weak bar and prominent bulge. There may also be a ring in the center. Though the spiral arms are somewhat asymmetric, the nucleus is fairly undisturbed. (ii) NGC 4314 ( $\sigma_e/v_g = 0.18$ ): This is a bright, early type galaxy with a strong bar and large bulge with a LINER type nucleus. There may be significant rotation in the nuclear region which may lower the  $\sigma_e$ . Also, the mass may be more widely distributed over the bulge and hence not as centrally concentrated as in NGC 3162. There appears to be a

ring of star formation in the nucleus as well (Gonzalez Delgado et al. 1997). Both galaxies are thus fairly normal and not unusually different from the rest of the sample galaxies.

Figures 1 and 2 suggest that galaxies with dynamically hotter nuclei have weaker bars. It is now well established that a galaxy's central black hole mass and bulge velocity dispersion are correlated (Ferrarese and Merritt 2000; Gebhardt et al. 2000). Later results show that the nuclear mass also correlates with the overall mass of a galaxy (Ferrarese et al. 2006; Hopkins et al. 2007). These results all indicate that the nuclear mass in a galaxy is intimately connected to the dynamics of its disk and halo. If so, then it is not surprising that  $\sigma_e$  in our sample of barred galaxies is correlated with  $Q_g$  or  $A_2$ . It suggests that the growth of a central mass and evolution of the bar for spiral galaxies may be closely linked.

Our results have important implications for the secular evolution of barred galaxies. Simulations suggest that there may be several factors responsible for the dissolution of a bar. One is the CMC growth (Hasan and Norman 1990; Friedli and Pfenniger 1991) which weakens the bar supporting  $x_1$  orbits and increases the fraction of chaotic orbits in the galaxy center. Second is the inflow of gas towards the galaxy center which results in the transfer of angular momentum to the bar wave which then weakens the bar itself (Bournaud et al. 2005). The buckling instability is an important bar thickening mechanism that results in a boxy/peanut bulge which can temporarily weaken a bar (Raha et al. 1991; Berentzen et al. 1998; Athanassoula and Misiriotis 2002; Martinez-Valpuesta et al. 2006; Debattista et al. 2006). All these effects result in a more massive and dynamically hotter central component and a weaker bar. The correlations that we see in Figs. 1 and 2 may be observational indications of this ongoing evolution. In particular, while the apparent drop of  $Q_g$  with central velocity dispersion might be an artifact caused by the bulge dilution effect (see Laurikainen et al. 2004; a bias could follow since nuclear velocity dispersion and bulge mass are strongly correlated), the similar correlation between the bar intensity contrast  $A_2$  suggest that the effect is real. The correlation between  $A_2$  and  $\sigma_e/v_g$  is also consistent with Das et al. (2003) who found that the bar ellipticity (closely related to  $A_2$ ) drops with central mass concentration.

The evolution of bars by secular processes in galaxies is an issue which is expected to gain more attention in the near future. Recent observational evidence shows that the fraction of strong bars in bright galaxies increases from under 10% at redshift  $z = 0.84$  to about 30% in the local universe (Sheth et al. 2008). Also, it has been shown by (Laurikainen et al. 2007) that among the early-type barred galaxies the bulge-to-total flux ratios are on average smaller than in the non-barred galaxies. These results, together with ours, may indicate that bars evolve with their parent galaxies.
